X-Ref References Category:Computer-aided design software Category:AutoCADIn a computer system, the system memory is typically in the form of dynamic random access memory (DRAM). In some computer systems, such as multiprocessor systems, the system memory is shared among the processors in the system. To prevent data collisions, it is desirable for the memory to be organized in a way that makes it possible to transfer ownership of the system memory to one of the processors without causing the other processors to lose their data. For example, a split-owner scheme is one memory organization in which a number of memory banks are organized to allow one processor to lock the entire memory bank while allowing other processors to access parts of the memory. In this manner, the memory can be used efficiently by the processors that need access to the memory. This can prevent the other processors from getting into a deadlock situation in which the other processors wait for access to memory that is inaccessible due to a lock placed on the memory by a first processor. In a conventional split-owner memory organization, each memory bank is assigned a fixed ownership state. The system is organized to control memory access based on the ownership state of the memory. This allows the memory bank to be accessed by a first processor that is assigned ownership of the memory bank. The other processors have only limited access to the memory and cannot access the memory until the first

processor relinquishes ownership of the memory bank. In a multiprocessor system, it is often desirable to run a single shared memory system for each processor in the system. The split-owner memory organization can also be used for the memory of the shared memory systems. However, in a shared memory system, the memory space assigned to one processor is allocated based on the amount of the memory space that is needed by the processor. In a shared memory system that uses the split-owner memory organization, the shared memory is divided into a number of memory banks that can be controlled by different processors. The shared memory system also includes a number of shared memory controllers that can access the memory banks. The memory controllers are typically coupled to a memory bus. Each memory controller can control one or more memory banks and access memory banks that have been assigned to it. Each memory bank includes a number of memory locations that can be accessed by any number of the memory controllers. The memory locations are accessed by the memory controllers through the memory bus. Each memory controller has a number of memory locations that are assigned to it a1d647c40b
